Keywords: sintered steels, carbSint, sintcarb, tensile strength

Abstract. The aim of this paper is to present experimental results on the evolution of tensile strength of some low alloyed steels function the copper content. There are prepared six types of mixtures as following: A1 (Fe), A2 (Fe+1.5%Cu), A3 (Fe+3%Cu), A4 (Fe+0.2%C), A5 (Fe+0.2%C+1.5%Cu), A6 (Fe+0.2%C+3%Cu). All six mixtures were pressed at 400, 500 respectively 600 MPa and the green parts were subjected to CARBSINT and SINTCARB thermal treatments. The influence of copper content, pressures and type of thermal treatments on the tensile strength was studied.

Introduction

Sintered steels occupy the largest place on the sintered parts field due to their wide use of these products. Copper is one of the most common alloy elements in the Powder Metallurgy (PM) field [1]. The addition of copper powder to the mixture of iron leads to increased mechanical strength and hardeness of the Fe/Cu sintered alloys. Generally, Cu content in the sintered steels is between (1.5- 4)% and improve the tensile strength in the range of 140-240 N/mm\(^2\) [6]. Also, presence of copper in the sintered steels composition has a positive influence on the machining of the sintered parts [2-5]. The present study is focused on the elaboration of sintered steels based on Fe/Cu by two types of thermal treatments (CarbSint and SintCarb) respectively on the tensile strength behavior of these steels function the elaboration parameters (compacting pressures, copper content, and thermal treatment)

Materials and experimental procedure

For the research were used six mixtures based on Fe, Cu, C and ZnSt as lubricant and the concentration of each mixture is presented in table 1.

*All powder mixtures have been added ZnSt as lubricant
All the mixtures were unilateral pressed in a die according MPIF Standard 10 to obtain green specimens for tensile strength respectively rectangular shape in order to calculate the density and porosity of the green specimens. Three pressures as 400, 500 and 600 MPa were used.

The densities and porosities were calculated with the relation 1, 2.

\[ \rho = \frac{m}{v} \, [g/cm^3] \]  \hspace{1cm} (1)

where: \( m \) = mass of the green part

\( v \) = volume of the green parts

\[ P = \left(1 - \frac{\rho_g}{\rho_t}\right) \times 100[\%] \]  \hspace{1cm} (2)

where: \( \rho_g \) = green density

\( \rho_t \) = theoretical density (7.8 g/cm\(^3\))

In fig. 2 is presented the evolution of the green density and in fig. 3 is presented the evolution of porosity function the compacting pressure and composition of the mixture.

According to the graph it is observed that the density increase with the increasing of the compacting pressures and the highest values of density were attained for the mixture A5 pressed at 600 MPa.

Porosity being complementary with the density this will decrease with the increasing of the compacting pressure.

The green specimens were subjected to thermal treatments as following:
- The CarbSint (CS) thermal treatment consists in heating up to 910 °C in argon atmosphere and maintaining at this temperature 45 minutes in CH\(_4\) atmosphere (carb) and then heating up to 1150 °C in argon atmosphere and maintaining for 60 minutes (sint), fig. 4;
- The SintCarb (SC) consists in heating up to 1150 °C in argon atmosphere, maintaining 60 minutes (sint), after that cooling up to 910 °C and maintaining for 45 minutes in CH₄ atmosphere (carb), fig. 5.

For the thermal treatments a Carbolite CWF 1200 oven was used. The samples were placed in a special box in order to ensure the inert gas (Ar) respectively the carburizing gas (CH₄), fig. 6.
Results and discussion

After the thermal treatments the samples were encoded as following: A1CS45 – sample obtained from mixture 1 and subjected to CarbSint treatment for 45 minutes; A1SC45 - sample obtained from mixture 1 and subjected to SintCarb treatment for 45 minutes.

In fig. 7-10 are presented the evolutions of the densities and porosities of the samples after thermal treatments.

The highest values for the densities of the sintered steels obtained by CS were attained for the samples A1CS45, A2CS45 respectively A3CS45, these samples not having in their composition
graphite. Also, the densities increase with the decreasing of copper content and the reason is that, the addition of Cu promote liquid phase sintering which results in increase in the volume of samples, and thus, the reduction of density.

The sintered steels obtained by SC have the highest values of densities comparative with the steels obtained after CS.

For all the samples were determined the tensile properties: strength (Rm), elongation (A) and maximum force (Fmax) using a LBG machine and the results are presented in fig. 11-16.

According to the graphs presented above the tensile strength parameters of the sintered steels obtained by both treatments (CS and SC) increase with the increasing of the compacting pressures.
The presence of copper in the steels composition leads to the increasing of strength and the steels with 3% Cu in their composition attained the highest values of strength.

Conclusions

According to the experimental results there can be drawn the following conclusions:
- Copper is an important element for the sintered steels and its presence in the composition of low alloyed steels improve the tensile strength of the material so the highest values for the tensile strength were attained for the samples CS and SC with 3% copper;
- Tensile strength behavior of carbon steel obtained by CS and SC was studied in comparison with conventional sintered carbon steel. In this context, two types of steels F-0000-15 and F-0000-20 was chosen because they have densities (6.7 g/cm$^3$ and 7.3 g/cm$^3$) close to the densities of the sintered steels obtained by CS and SC. According to ASTM B 783-04, these two types of steels have the strength equal to 100 N/mm$^2$ respectively 140 N/mm$^2$ which are lower comparative with the values of strength obtained for the steels obtained by CS and SC (105 up to 275 N/mm$^2$)
